ABSTRACT

Background - The traditional diet of Oman which comprises primarily of dates, milk, rice, brown bread, fish and vegetables has changed considerably to resemble a Western diet which is high in calorie, high glycaemic index carbohydrates, total fat and saturated, trans and omega 6 fatty acids, and low in omega-3 fatty acids and essential micronutrients.

Aim - To investigate fat-soluble nutrient (vitamin A, D, E and beta carotene) status of Omani school children before and after intervention with fish diet and docosahexaenoic acid (DHA)-enriched fish oil supplement.

Method - Three hundred fourteen children aged between 9 and 10 years were recruited from three schools in Muscat. The schools were randomly assigned to fish, fish oil or control group and the children given 100 g lightly grilled fish (fish group), omega-3 capsule containing 403 mg DHA and 53 mg eicosapentaenoic acid (EPA) or their habitual diet. Baseline body weight, height and body mass index were assessed and a non-fasting blood sample collected at baseline and after 12 weeks of intervention.

Results – Mean plasma vitamin A, beta carotene, vitamin E concentrations and vitamin E/total lipid ratio at baseline were 2.7±0.85 μmol/L, 0.68±0.48 μmol/L, 21.1±4.8 μmol/L and 5.0±0.81 μmol/mmol respectively. None of the children were deficient in either of the nutrients and there was no gender difference. Most of the children were severely deficient (<27.5 nmol/L; 10.5% boys and 28.5% girls), deficient (27.5-44.9 nmol/L; 47.6% boys and 49.4% girls) or insufficient (50 – 74.9 nmol/L; 34.6% boys and 21.5% girls) in vitamin D. Only 7.3% boys and 0.6% girls had optimal status (≥ 75 nmol/L). Parathyroid hormone (5.0±1.7 vs. 5.8±2.1 pmol/L; p<0.0001) and alkaline phosphatase (225.2±66.6 vs. 247.8±73.7 U/L; p<0.01) levels were lower in the boys than in the girls. After 12 weeks intervention, the fish oil (1.2±0.70 μmol/L) and fish (1.20±0.7 μmol/L) groups compared with the placebo
(0.85±0.43 μmol/L) had higher concentrations of beta carotene (p<0.0001). Similarly, the children who received fish oil (54.1±17.5 nmol/L; p<0.001) and fish (49.2±17.4 nmol/L; p<0.05) had elevated levels of vitamin D than those who did not (42.3±17.5 nmol/L).

**Conclusion** – This study demonstrate that vitamin D insufficiency is highly prevalent in Omani young school children and it can be mitigated with omega-3 fatty acid supplementation. Vitamin D plays a crucial role in skeletal and extraskeletal systems. Therefore, there is an urgent need for a well-thought-out programme which incorporates a fortification of foods and drinks favoured by children and outdoor activities to help tackle this major public health problem.
INTRODUCTION

Oman has made a remarkable progress in socio-economic development in the last four decades (Musaiger 1998, Ibpus 2013). This advancement is reflected in dramatic reductions in maternal, child and infant mortality rates, common infectious diseases, extreme poverty, and a significant increase in life expectancy (UNICEF 2009, Al-Lamki 2010, and UNDP 2010). Conversely, the prevalence of obesity in adults and children, and non-communicable diseases, such as vascular and respiratory diseases, diabetes and cancer has reached epidemic proportions (Musaiger 2002, Badran and Laher 2011, Abdul Rahim et al 2014). The Oman World Health Survey, a country-wide community-based household survey involving about 5000 subjects conducted in 2008, revealed that 40.3% of those surveyed had hypertension, 12.3% diabetes, 21.4% obesity and 33.6% elevated blood cholesterol (Al Riyami et al 2012).

It is plausible that genetic predisposition may be a factor for the rise in non-communicable diseases in Oman and the other Gulf countries. However, the fact that the rise occurred in a short time and coincided with a period of economic prosperity suggests that modifiable lifestyle factors, such as physical inactivity, smoking and unhealthy diets could be the main culprits. Indeed, it has been reported that the traditional diet of the gulf countries which comprises primarily of dates, milk, rice, brown bread, fish and vegetables (Musaiger 1998, Galal 2002) has changed to resemble a more Western diet which is high in vegetable oils and animal fat (~30% daily calorie), refined sugar (~51% daily calorie) and low fibre cereals (mainly highly extracted wheat flour and polished rice, 35-42% of daily energy) (Musaiger 1998, Badran and Laher 2011). The Western diet is high in calorie, high glycaemic index carbohydrates, total fat and saturated, trans and omega-6 fatty acids, and low in omega-3 fatty acids and essential micronutrients.

Childhood dietary habits tend to track to adult life (Mikkila et al 2004, Ventura and Worobey 2013) and some of the non-communicable chronic diseases are thought to begin in early life.

Recently, we conducted a comprehensive study designed to define health, physical fitness and cognitive ability of school children within the context of the rapid nutrition transition in Oman. This communication reports plasma fat-soluble micronutrient status at baseline and after intervention with fish-based menu or docosahexaenoic acid (DHA) enriched fish oil supplement.

SUBJECTS AND METHODS

Subjects and Recruitment

Three hundred fourteen children (boys, n=139, Girls, n=175) accounting for a 4.6% of the school pupils aged between 9 and 10 years from the Muscat Governorate were recruited using a two stage sampling procedure. In the first stage, three (n=3) of thirty nine (n=39) schools in the Governorate and in the second stage, three Grade 4 classes from five were randomly selected. The three schools were assigned to fish, fish oil or control group and the children were given for lunch a 100 gram lightly grilled fish sandwich with some vegetables (fish group), their habitual food or omega-3 fatty capsule containing 403 mg docosahexaenoic (DHA) and 53 mg eicosapentaenoic (EPA) acids. One hundred gram (100g) of the fish used in the study (Grouper, Sea bream, Kingfish, Emperor and Snapper) provided 150 to 200 mg
omega-3 fatty acids and the dishes were prepared tastefully to enhance compliance by professional chefs at the Intercontinental City Hotel, Muscat. Body weight, height and body mass index were assessed baseline and a non-fasting blood sample, about 8 ml, obtained in EDTA at baseline and after 12 weeks of intervention.

The study was approved by the Research Ethics Committee of the Ministry of Health, Sultanate of Oman (Ref. MH/DGP/R&S/Proposal_Approved/8/2012), and the National Research Ethics Committee North West – Haydock, UK (REC reference no. 12/NW/0760) and registered with ISRCTN Register (Reg. No. ISRCTN93233285). Informed and signed consent was obtained from the parents/guardians of the children and the study was conducted in accordance with the provisions of the ethical approval of the two ethics committees and the principles of Helsinki Declaration.

Methods

Sample processing – Plasma and red blood cells were separated from whole blood specimen by centrifugation at 1200 g, 4°C, for 10 minutes. The plasma was siphoned out carefully and transferred to another tube. The buffy coat was discarded and the red cell pellet washed three times by suspension in physiological saline (0.85% NaCl) and cold centrifugation. The plasma and red blood cells were stored at -70°C until analysis.

Anthropometry - Weight in kilogram and height in centimetre were assessed with a Seca Electronic Scale 890 (UNISCALE, Seca, Birmingham B5 5QB, UK) and a measuring board (Schorr, Weight and Measure, LLC, Olney, Maryland, USA) respectively.

Plasma vitamin A and vitamin E and beta carotene analyses – An aliquate of 200 μL of plasma in duplicate was used for analysis. The plasma was deproteinised by with 4 ml of absolute ethanol and vortexing thoroughly for 3 minutes. Subsequently, 10 ml of hexane was
added to the plasma-ethanol mixture, vortexed for 3 minutes and centrifuged at 1200 g, 4°C, for 10 minutes. The top organic layer containing the required analytes was carefully transferred to another tube, dried at 30°C under a gentle stream of nitrogen, suspended in 1000 μL of methanol containing 0.01% butylated hydroxytoluene. An aliquate, 50 μL, was taken for analysis. The target analytes (retinol, alpha-tocopherol and beta carotene) were separated by Agilent 1100 high-performance liquid chromatography (HPLC) system (Agilent Technologies, Waldbronn, Germany) with the use of a 5 micron C18 reverse-phase column, 150 X 4.6 mm, (HiChrom Limited UK). The analytes were eluted with 100% HPLC grade methanol at a flow rate of 2 ml/min and detected with a diode array UV/Vis detector (Agilent Technologies, Waldbronn, Germany). Vitamin A, vitamin E and beta carotene were detected at 325 nm (1.5 min), 292 nm (4.8 min) and 453 nm (30 min). Concentrations were determined from a standard curve computed with the use of ChemStation (Agilent Technologies, Waldbronn, Germany).

**Plasma triglycerides** – Concentration of plasma triglycerides was determined enzymatically (Glycerol phosphate oxidase assay) based on the method described by Fossati and Prencipe (1982) and McGowan et al (1983) with the use of a reagent kit supplied by Abbot Laboratories (Ref: 7D74-21, 304350/R1, Abbott, Max-Planck-Ring 2, 65205 Wiesbaden, Germany).

**Plasma cholesterol** – An enzymatic method (cholesterol esterase- cholesterol oxidase-peroxidase) described by Roeschlaeu and Allain (1974) with a reagent kit obtained from Abbott Laboratories (Ref: 7D62-21, 304342/R1, Abbott, Max-Planck-Ring 2, 65205 Wiesbaden, Germany) was used to analyse total cholesterol.

**Vitamin D (25-hydroxy vitamin D)** - Plasma total vitamin D, 25-hydroxylated cholecalciferol (vitamin D3) and ergocalciferol (vitamin D2), was determined with a competitive electrochemiluminescence protein binding assay (Abdel-Wareth et al 2013).
using the Cobas e 601 immunoassay auto-analyser and reagents obtained from Roche Diagnostics (Sandhoferstrasse, Mannheim, Germany).

**Parathyroid Hormone (PTH)** – Intact plasma PTH was quantified by Architect Intact PTH assay, a two-step chemiluminescent microparticle immunoassay, using the automatic immunoassay analyser ARCHITECT i2000SR (Abbott, Abbott Park, IL, USA) and reagents from Abbott Diagnostics (Ref: 8K25, 84-6434/R5, Abbott, Max-Planck-Ring 2, 65205 Wiesbaden, Germany).

**Alkaline Phosphatase (ALP)** – ALP was measured on an Architect c8000 analyser (Abbott Diagnostics, Abbot Park, Il, USA) with a reagent kit supplied by Abbott Diagnostics (Ref: 7D61-20, 30-3979/RS, Abbott, Max-Planck-Ring 2, 65205 Wiesbaden, Germany).

**Calcium** – Plasma total calcium was determined with the use of an Architect c8000 analyser (Abbott Diagnostics, Abbot Park, Il, USA) with the Arsenazo III dye binding method and a reagent kit from Abbott Diagnostics (Ref: 7D61-20, 30-3979/RS, Abbott, Max-Planck-Ring 2, 65205 Wiesbaden, Germany).

**Phosphate** – Plasma inorganic phosphate was analysed based on the Molybdenum blue colorimetric method with a reagent kit obtained from Abbott Laboratories (Ref: 7D71-20 and 7D71-30, 30-3926//R5, Abbott, Max-Planck-Ring 2, 65205 Wiesbaden, Germany) using the ARCHITECT c8000 auto-analyser (Abbott, Abbot Park, IL. USA).

**Data Analyses**

The data are expressed as mean and standard deviation (S.D.). Independent (unpaired) and paired t-tests, respectively, were used to determine statistical significance between the genders at baseline and between pre- and post-intervention within gender. Group comparison was performed with a one-way ANOVA, and Boneferroni post hoc test when a significant
difference is indicated. Differences were considered significant if the p value was less than 0.05. All analyses were carried out with SPSS version 21 (IBM SPSS, IBM Corporation, Armonk, NY, USA).

RESULTS

Pre-intervention (baseline) gender comparison

Body weight, height, body max index and plasma vitamin A (all-trans retinol), beta carotene, vitamin E (alpha-tocopherol), total lipid (triglycerides and cholesterol), alpha-tocopherol and total lipid ratio, total vitamin D, parathyroid hormone, alkaline phosphatase, calcium and inorganic phosphate levels of the children are shown in Table 1. The male compared with the female students had higher vitamin D (p<0.0001) and lower parathyroid hormone (p<0.0001) and alkaline phosphatase (p<0.01) levels.

Post-intervention group comparison

Compared with the control group, the children (both male and female students) who were given fish oil supplement for twelve weeks had increased concentrations of beta carotene and vitamin D (p<0.001). Similarly, both carotene (p<0.001) and vitamin D (p<0.05) levels were higher in those who received fish meals (Table 2).

Gender-stratified post-intervention group comparison

In the male students, beta carotene and vitamin D concentrations in the fish oil (p<0.001) and in the fish (p<0.05) groups were higher than in their counterparts who did not receive fish oil or fish meals (Table 3). Likewise, in the female students who were given fish oil and fish meals had elevated level of vitamin D (p<0.001 and p<0.05) compared with the control group students (Table 3).
Pre- and post-intervention comparison

Post-intervention plasma vitamin D (Fig. 1) and parathyroid hormone (Fig. 2) concentrations compared with pre-intervention (baseline) were higher in the children who received fish oil and fish meals (p<0.0001). There was no difference between the pre- and post-intervention concentrations of the two analytes in the control group.

DISCUSSION

Urbanisation, heavy reliance on imported foods (primarily beef, dairy and poultry products and refined cereals, vegetable oils and sugar) and sweetened beverages and the proliferation of food supermarkets and convenience fast-food restaurants have led to a drastic change in dietary habits in Oman. The impact of the change, which is characterised mainly by intakes of calorie-rich and essential micronutrient-poor foods, on lipid-soluble nutrient (vitamin A, D and E, and beta carotene) status of Omani children has not been fully investigated. Accumulating evidence demonstrates, these micronutrients, in addition to their well-characterised classical functions (Goodman et al 1966, Bonet et al 2003, DeLuca 2004, Black et al 2008, Sathe and Patel 2010, Nike and Traber 2012) play a role in gene expression (Zhang et al 1992, Azzi et al 2004, Bastien and Rochette-Egly 2004, Hossein-nezhad et al 2013), cognitive function (Grodstein et al 2007, Olson and Mello 2010, Soni et al 2012, Ulatowski et al 2014) and antioxidant defense (Burton and Ingold 1984, Lin et al 2005). Moreover, deficiency/insufficiency of these nutrients is thought to be associated with increased risks of non-communicable diseases.

A biannual supplementation programme with a high dose vitamin A in infants and children aged six to fifty-nine months (UNICEF 2007, WHO 2011a) is effective in reducing morbidity, mortality and vision impairment (Beaton et al 1993, Fawzi et al 1993, Imdad et al
Regardless, vitamin A deficiency is still the foremost cause of these preventable problems, particularly in South East Asia and Africa. Based on the prevalence of night blindness and biochemical vitamin A deficiency based estimates, 45 and 122 countries respectively have vitamin A deficiency of public health significance (WHO 2009). A 0.70 μmol/l serum/plasma vitamin A concentration is the cut-off point of deficiency (WHO 1996, De Pee and Dary 2002) which is used as a marker for assessing severity and public health significance in most age groups (WHO 2011b). A cross-sectional survey (MHO 2006) on food fortification and micronutrient deficiencies conducted in Oman in 2004 found vitamin A deficiency in children aged 6-59 (5.5%), 6-23 (18%) and 24-59 (3%) months, and in non-pregnant women of reproductive age (0.5%). In the current study, deficiency (≤ 0.70 μmol/l) was not detected in any of the children and only three of them had a marginal status (<1.05 μmol/l). Some of the milk and dairy products in the Omani market are fortified with vitamin A (Alasfoor et al 2007) and it is mandatory for edible vegetable oils sold in the country to incorporate 60 IU/g of the vitamin. It appears that the children were able to maintain adequate status by consuming foods fortified with preformed vitamin A as well as vegetables containing provitamin A.

There is a wide variability in blood beta carotene concentration among healthy individuals (Winklhofer-Roob et al 1997). The variations are primarily a reflection of intake, vitamin A status and genetic make-up (Lacher et al 2005, Tourniaire et al 2009, Borel 2012). Gender-related differences in concentration have also been reported (Hercberg et al 1994, Olmedilla et al 1994). Nevertheless, depending on the amount of fruits and vegetables consumed, blood beta carotene levels generally fall between 0.2 and 1.5 μmol/l (Burri 1997). The present study did not detect gender-related effect on plasma beta carotene, and the values were within the aforementioned range in 87% (0.63±0.31 μmol/l), below in 7% (0.16±0.04 μmol/l) and above in 6% (1.87±0.28 μmol/l) of the children. Fresh fruits, which are an important component of
the Omani foods, are eaten three or more times a week (Opara et al 2007). This Omani dietary habit may provide an explanation for the ‘adequate’ beta carotene status in most of the children in the current study.

In contrast to vitamin A, the concentration of plasma beta carotene increased significantly in the fish diet and fish oil groups after intervention for 12 weeks (Table 2). This finding, which is consistent with the report that fish oil supplementation enhances the absorption of beta carotene in human (Nair et al 1993) and rats (Blakely 1992), is rather intriguing since dietary fat is thought to facilitate fat-soluble vitamin uptake and transport at the intestinal level.

As is the case with the other fat-soluble vitamins, the blood level of vitamin E (alphatocopherol) varies considerably between individuals and population groups (Winklhofer-Roob et al 1997, Valtueña et al 2011, Péter et al 2013, Traber 2014). Nevertheless, a concentration of less than 12 μmol/l in plasma is defined as a cut-off point of vitamin E inadequacy (IOM 2000) and the minimum concentration required to help prevent cardiovascular diseases and cancer is thought to be 30 μmol/l (Gey 1995). 96.6% of the children in this study had concentrations higher and 3.4% lower than the cut-off point (12 μmol/l). Two children had levels (7.38 and 7.89 μmol/l) less than 8 μmol/l, a value which is associated with neurological disease. Since vitamin E is intimately associated with circulating lipids, the ratio of the two nutrients was used to evaluate vitamin E status. All of the children had vitamin E/total lipid ratio higher than the cut-off point 1.11 μmol/mmol suggesting that the ‘deficiency’ in the 3.4% of the children indicated by plasma vitamin E concentration may not be related to a low intake.

There was no difference in the post-intervention plasma vitamin E concentration between the three groups (Table 2, 3 and 4). In contrast, the post-intervention vitamin E/total lipid ratio was significantly higher in the children who received the fish oil supplement compared with the fish diet and control groups. This difference was most likely due to the combined effect of
omega-3 fatty acids which reduces blood lipid content and the vitamin E incorporated in the supplement to prevent lipid peroxidation.

Consistent with the previous reports of Omani non-pregnant (Al-Kindi 2011) and pregnant (Al Kalbani et al 2011) women, school children aged 9 to 12 years (Kilani et al 2013) and adults aged 18 to 55 (Abiaka et al 2013), most of the children in the current study were severely deficient (<27.5 nmol/L; 10.5% boys and 28.5% girls), deficient (27.5-44.9 nmol/L; 47.6% boys and 49.4% girls) or insufficient (50 – 74.9 nmol/L; 34.6% boys and 21.5% girls) in vitamin D. Only 7.3% boys and 0.6% girls had a sufficient level (≥ 75 nmol/L) level. As it is borne out by the elevated levels of parathyroid hormone and alkaline phosphatase (Table 1) the insufficiency was more pronounced in the female children. The high prevalence of vitamin D deficiency in the children should be a major public health concern because childhood is a period of skeletal mineral acquisition and bone modelling and there is evidence that vitamin D plays a critical role in muscle growth and development, cognitive function and modulation of innate and adaptive immunity.

Omega-3 fatty acids have been shown to enhance bone mineralisation in human and experimental animals but their effect on blood vitamin D has not been investigated. The children who were given oily fishes, which are thought to contain variable amounts of vitamin D, and DHA-enriched fish oil supplement, which was stripped out of vitamin D, had elevated plasma 25-hydroxy vitamin D concentration compared with the control group (Table 2, 3, 4). It is not obvious how fish oil increases plasma vitamin D. However, since it did not have any effect on PTH or alkaline phosphatase the action may be mediated by the facilitation of vitamin D transport across the intestinal mucosa. Indeed, there is evidence that dietary fat promotes vitamin D absorption (Dawson-Hughes et al 2014).

Bone mineral density of the children and vitamin D status of rural children with limited access to school transport were not assessed. These limitations will be addressed in future
investigations. This study demonstrates that vitamin D insufficiency is highly prevalent in Omani young school children and it could be mitigated with omega-3 fatty acid supplementation. Various studies have reported vitamin D deficiency/insufficiency in non-pregnant and pregnant Omani women. It is conceivable that Omani children may be at risk of developmental and health problems caused by prenatal and postnatal vitamin D deficiency. Vitamin D plays a crucial role in skeletal and extraskeletal systems. Therefore, there is an urgent need for a well-thought-out programme which incorporates a fortification of foods and drinks favoured by children and outdoor activities to help tackle this major public health problem.
ACKNOWLEDGEMENTS

Very sincere thanks are due to the children, parents, teachers and headmistresses of the schools for their participation and support, staffs and management of the Ministries of Agriculture and Fisheries Wealth, Health and Education who helped with the design, implementation and monitoring of the study, Dr Manal Al Kindi and colleagues in the pathology laboratory, Royal Hospital, for blood sample processing and biochemical assay, members of Seeb Polyclinic for blood specimen collection, catering service team of Intercontinental Hotel for preparing fish meals and Sheikh Saif Sultan Mohammed Al Habsi for providing transport. In addition, we are very grateful to Mr Peter Clough and Efamol Ltd. UK for providing omega-3 capsules for the study free of charge. The study was supported by the 8th Five Year Development Plan, Ministry of Agriculture and Fisheries Wealth, Sultanate of Oman.
