A Nonlinear Panel Unit Root Test under Cross Section Dependence

Mario Cerrato^a, Christian de Peretti^b, Nicholas Sarantis^c

November 2007

Abstract

We propose a nonlinear heterogeneous panel unit root test for testing the null hypothesis of unit-root processes against the alternative that allows a proportion of units to be generated by globally stationary ESTAR processes and a remaining non-zero proportion to be generated by unit root processes. The proposed test is simple to apply and accommodates cross section dependence. Monte Carlo simulations shows that our test holds correct size and under the hypothesis that data are generated by globally stationary ESTAR processes has a better power than the recent linear test proposed in Pesaran (2005). An application to a panel of bilateral real exchange rates with the US Dollar from the 20 major OECD countries is provided.

1. Introduction

There is now a large literature on testing for unit roots in economic and financial variables employing a variety of time series and panel tests¹. The growth in that area is mainly due to empirical applications on, for example, Purchasing Power Parity (PPP) and Growth (see Cerrato and Sarantis, 2007a, 2007b; and Emerson and Kao, 2006, amongst others).

A weakness of the existing univariate and panel unit root tests is that they are based on the assumption that the underlying variable follows a linear process. However economic theory suggests that many variables exhibit nonlinear behaviour. For example, a number of theoretical models in international macroeconomics formalise the notion of nonlinear exchange rate behaviour due to transaction costs (e.g. Dumas, 1992; Sercu *et al*, 1995; O'Connell, 1998; Goswami *et al*, 2002)², while others describe currency and financial crises as non-linear processes (e.g. Jeanne and Masson, 2000; Chang and Velasco, 2001). In growth economics, a number of theoretical models suggest that economic growth is a nonlinear process with the economy bouncing back and forth between different regimes (e.g. Zilibotti, 1995; Peretto, 1999; Matsuyama, 1999; Galor *et al*, 2000)³. Theoretical models in finance highlight heterogeneous expectations (e.g. Brock and Hommes, 1998; De Grauwe and Grimadi, 2005), heterogeneity in investors' objectives (e.g. Peters, 1994), and herd behaviour (e.g. Lux, 1995) as some of the sources of nonlinearity in asset prices.

If economic and financial variables exhibit nonlinear behaviour, the standard unit root tests that are based on a linear AR process will have low power. Two recent papers, Sollis *et al* (2002) and Kapetanios *et al* (2003), address this issue by developing formal unit root tests against the alternative of nonlinear mean reversion. Both papers examine the unit root hypothesis against the nonlinear STAR (smooth transition autoregressive) alternative and show that, under the null hypothesis, the distribution of the respective tests is not normal. As a result the two papers employ Monte Carlo simulations to obtain critical values. The main difference between the two tests is that Sollis *et al* use a logistic transition function (LSTAR) while Kapetanios *et al* use an exponential transition function (ESTAR).

However both these nonlinear unit root tests are univariate and, consequently, will still suffer from low power in the case of small samples. In this paper we extend the Kapetanios *et*

¹ For a review of the various unit root tests see, for example, Breitung and Pesaran (2007) and Cerrato and Sarantis (2007b).

² For empirical studies on nonlinear exchange rate models, see Michael *et al*, (1997), Sarantis (1999), Taylor *et al* (2001), and Rapach and Wohar (2003), among others.

³ A number of authors have also undertaken empirical investigations of nonlinear growth models; see, for example, Fiaschi and Lavezzi (2007), Liu and Stengos (1999) and Durlauf and Johnson (1995).

al nonlinear unit root test to a panel context in order to address the low power problem of univariate tests. Since heterogeneous cross-section dependence tends to be important in most empirical applications, we employ the Pesaran (2005) panel unit root framework that enables us to account for heterogeneous cross-section dependence in a novel way. Pesaran (2005) shows that the individual CADF (Cross Augmented Dickey Fuller) and the panel statistic (CIPS) have non-normal distributions, so their critical values (for different N and T) are obtained by Monte Carlo simulations. The panel unit root test proposed by Pesaran (2005) differs from other tests such as Choi (2001) and Hadri (2000) in that while the latter all assume that individual time series are independent, Pesaran (2005) shows that cross sectional dependence can be accounted for by augmenting the standard DF regression with the cross section averages of lagged levels and first differences of the individual series.

In this paper we propose a novel nonlinear panel unit root test that extends both the univariate nonlinear tests and the linear panel unit root tests, thus filling an important gap in the existing literature. Since the panel nonlinear statistic has a non-normal distribution, we use Monte Carlo simulations to analyse the size and power of the test under different scenarios, and we calculate critical values which can be used in future applications of the test. We also illustrate the applicability of our test by applying it to a panel of bilateral real exchange rates.

The rest of the paper is organised as follows. Section 2 specifies the nonlinear dynamic panel model with cross-section dependence. Section 3 derives the individual and panel nonlinear unit root tests, and then uses stochastic simulations to obtain the distributions of these statistics and critical values. Section 4 analyses the size and power of the panel nonlinear unit root test under alternative scenarios and compares the results to the performance of the linear Pesaran (2005) test. Section 5 reports the results from an application to real exchange rates, while Section 6 concludes.

2. A Nonlinear Dynamic Panel with Cross-Section Dependence

Suppose the observation y_{it} on the i^{th} cross-section unit at time t is generated according to the dynamic nonlinear heterogeneous panel ESTAR model below:

$$y_{it} = \beta_i y_{i,t-1} + \nu_i y_{i,t-1} Z(\theta_i; y_{i,t-d}) + u_{it}, \quad t = 1, \dots, T, \quad i = 1, \dots, N, \quad (1)$$

where initial value, y_{i0} , is given, and the error term, u_{it} , has the one-factor structure:

$$u_{it} = \gamma_i f_t + \varepsilon_{it} \quad \varepsilon_{it} \approx i.i.d.(0, \sigma_{\varepsilon_i}^2) \quad (2)$$

in which f_t is the unobserved common effect, and ε_{it} is the individual-specific (idiosyncratic) error. Following the literature on STAR models, the transition function adopted here is of the exponential form, i.e.,

$$Z(\theta_i; y_{i,t-d}) = 1 - \exp(-\theta_i y_{i,t-d}^2) \quad (3)$$

where we assume that $\theta_i \geq 0$, and $d \geq 1$ is the delay parameter. To begin with we assume that y_{it} is a mean zero stochastic process. We discuss processes with nonzero mean and later. To simplify the model and following the existing literature, the delay parameter d is set to be equal to one and (1)-(3) are re-written in first difference form as:

$$\Delta y_{it} = \phi_i y_{i,t-1} + \nu_i y_{i,t-1} [1 - \exp(-\theta_i y_{i,t-1}^2)] + \gamma_i f_t + \varepsilon_{it}, \quad (4)$$

where $\phi_i = -(1 - \beta_i)$. If y_{it} is assumed to follow a unit root process in the middle regime, then $\phi_i = 0$,⁴ and equation (4) can be re-written as:

$$\Delta y_{it} = \nu_i y_{i,t-1} [1 - \exp(-\theta_i y_{i,t-1}^2)] + \gamma_i f_t + \varepsilon_{it} \quad (5)$$

Using (5), we are interested in testing the hypotheses:

$$H_0: \theta_i = 0 \quad \text{for all } i \quad (5a)$$

against the possibly heterogeneous alternatives,

$$H_a: \theta_i > 0 \quad \text{for } i = 1, 2, \dots, N_1; \quad \theta_i = 0 \quad \text{for } i = N_1 + 1, N_1 + 2, \dots, N \quad (5b)$$

Remark 1: The alternative hypothesis above implies that some units are generated by a stationary ESTAR model but it also allows a proportion of units being a unit root process.

⁴ It follows the practice in the literature (e.g. Balke and Fomby, 1997, in the context of TAR models and Michael *et al.*, 1997 in the context of ESTAR models).

The following assumptions are introduced:

Assumption 1: $N_1 / N \rightarrow q$ as $N \rightarrow \infty$, with $0 < q \leq 1$ under the alternative hypothesis.⁵

Assumption 2: ε_{it} are independently distributed for all $i = 1, \dots, N$ and $t = 1, \dots, T$, with zero mean, constant variance $\sigma_{\varepsilon_i}^2$, and finite fourth order moment.

Assumption 3: f_t is serially uncorrelated with zero mean, constant variance σ_f^2 , and finite fourth moment. (Without loss of generality σ_f^2 will be set equal to unity.)

Assumption 4: ε_{it} , f_t , and γ_i are independently distributed for all i .

Assumption 5: Following Pesaran (2004a), we define the weights $\{\varphi_i\}$ having the following

properties: $\varphi_i = O(\frac{1}{N})$; $\sum_{i=1}^N \varphi_i = 1$; $\sum_{i=1}^N |\varphi_i| < K$ for $K < \infty$; $\sum_{i=1}^N \varphi_i^2 = O(\frac{1}{N})$.

Assumption 6: Let $\bar{\gamma} = \frac{1}{N} \sum_{j=1}^N \gamma_j$. We suppose $\bar{\gamma} \neq 0$ for a fixed N and for $N \rightarrow \infty$.

3. Nonlinear Unit Root Tests with Serially Uncorrelated Errors

Assumptions 1 and 2 together imply that the composite error, u_{it} , is serially uncorrelated. This restriction will be relaxed in Section 3.3.

3.1 Individual NCADF Test

Testing the null hypothesis (5a) directly is not feasible, since ν_i is not identified under the null.⁶ To overcome this problem, we follow Luukkonen et al. (1988), and derive below a t -type test statistic. Using Taylor expansion on (5), under the null hypothesis, the following auxiliary regression is obtained:

$$\Delta y_{it} = a_i + b_i y_{i,t-1}^3 + \gamma_i f_t + e_{it}. \quad (6)$$

Lemma 1: If Assumptions (2)-(6) are satisfied, then the common factor f_t can be approximated by:

⁵ As noted in Im, Pesaran and Shin (2003) this condition is necessary for the consistency of the panel unit root tests.

⁶ See for example Davies (1987).

$$f_t \approx \frac{1}{\gamma} \Delta \bar{y}_t - \frac{\bar{w}_t}{\gamma} \bar{y}_{t-1}^3 \quad (7)$$

Proof: see Appendix 1.

Therefore, it follows that Equation (6) can be written as the following nonlinear cross-sectionally augmented DF (NCADF) regression:

$$\Delta y_{it} = a_i + b_i y_{i,t-1}^3 + c_i \Delta \bar{y}_t + d_i \bar{y}_{t-1}^3 + e_{it} \quad (8)$$

The idea is, given the framework above, to develop a unit root test in heterogeneous panel model based on Equation (8). Extending the idea in Kapetanios *et al.* (2003), we suggest using model (8) and t -statistic on b_i , that is denoted by

$$t_{iNL}(N, T) = \frac{\hat{b}_i}{s.e.(\hat{b}_i)}, \quad (9)$$

where \hat{b}_i is the OLS estimate of b_i , and $s.e.(\hat{b}_i)$ its associated standard error. Denote the student statistic on the ratio of b_i in Equation (8) as:

$$t_{iNL}(N, T) = \frac{y'_{i,-1} M \Delta y_i}{(\Delta y_i' M \Delta y_i)^{1/2} (y'_{i,-1} M y_{i,-1})^{1/2}} \quad (10)$$

where $\Delta y_i = (\Delta y_{i1}, \Delta y_{i2}, \dots, \Delta y_{iT})'$, $y_{i,-1}^3 = (y_{i,0}^3, y_{i,1}^3, \dots, y_{i,T-1}^3)'$, $X = (\tau, \Delta y_i, y_{i,-1})'$, M the projection matrix onto $\delta(X)$, the orthogonal complement of the span of X , $\tau' = (1, 1, \dots, 1)$ and $\Delta \bar{y} = N^{-1} \sum_{j=1}^N \Delta y_j$, $\bar{y}_{i,-1} = N^{-1} \sum_{j=1}^N y_{j,-1}$. The critical values of the NCADF test can be computed by stochastic simulation for any fixed $T > 3$, and for given distributional assumptions for the random variables $(\varepsilon_{it} f)$.

To accommodate stochastic processes with nonzero means, we need the following modifications. In the case where the data has nonzero mean, i.e., where $x_t = \mu + y_t$, we use the de-meaned data $y_t = x_t - \bar{x}$, where \bar{x} is the sample mean. In this case the asymptotic distribution of the t_{NL} statistic is basically the same as (10), except that data are replaced by the de-meaned data.⁷

Figure 1 displays the simulated cumulative distribution function of the individual NCADF statistic under the null hypothesis using 50,000 replications for $N = 100$ and $T = 500$. For comparison the simulated cumulative distribution function of Pesaran CADF statistic is also provided. The series $y_{i,t} = y_{i,t-1} + f_t + u_{i,t}$, for $i = 1, 2, \dots, 100$, and $t = -50, -49, \dots, 1, 2, \dots, 500$ were first generated from $y_{i,-50} = 0$, with f_t and $u_{i,t}$ as *i.i.d.* $N(0,1)$. Then 50,000 NCADF regressions of $\Delta y_{i,t}$ on $y_{i,t-1}$, $\Delta \bar{y}_t$, and \bar{y}_{t-1} . $\Delta \bar{y}_t$ and \bar{y}_{t-1} were computed over the sample $t = 1, 2, \dots, 500$. Figure 1 plots the ordered values of the OLS t -ratios of $y_{i,t-1}$ in these regressions.

Not surprisingly the nonlinear CADF distribution, as the Pesaran's CADF distribution, is more skewed to the left as compared to the standard DF distribution. This is clearly reflected in the critical values of the distributions summarized in Table 1. Critical values of the individual nonlinear CADF distribution for values of T and N in the range of 10 to 200 are given in Appendix 2.

The nonlinear CADF distribution, like the Pesaran's CADF distribution and the standard DF distribution, departs from normality in two important respects: it has a substantially negative mean and its standard deviation is less than unity, although not by a large amount. The simulated density functions of the standardized NCADF, computed with $N = 100$, $T = 500$, and 50,000 replications are displayed in Figure 2. The mean, standard deviation, skewness and Kurtosis coefficients of the NCADF and the Pesaran's CADF distributions are reported in Table 2. They are quite small, although statistically highly significant.

Since cross-sectional dependence in panel data is widely known now to be a serious problem, in the next sections we shall be using model (6) to develop a unit root test to test for the null hypothesis of unit root against an ESTAR stationary alternative.

⁷ Similarly, for the case with nonzero mean and nonzero linear trend, i.e., where $x_t = \mu + \delta t + y_t$, we use the de-meaned and de-trended data $y_t = x_t - \hat{\mu} - \hat{\delta} t$, where $\hat{\mu}$ and $\hat{\delta}$ are the OLS estimators of μ and δ . Now the associated asymptotic distributions are such that $W(r)$ is replaced by the de-meaned and de-trended standard Brownian motion $W(r)$.

3.2 Panel Nonlinear CADF Test

Following Pesaran (2005), we suggest using the t -statistic in Equation (10) to construct a panel unit root test by averaging the individual test statistics:

$$\bar{t}_{NL}(N, T) = N^{-1} \sum_{i=1}^N t_{iNL}(N, T) \quad (11)$$

This is a nonlinear cross-sectionally augmented version of the IPS test based (NCIPS). The test statistic defined in Equation (11) can also be extended to the case where serial correlation is present in the data. In this particular case, one may include, in the model, lags of the left hand side variable after using an information criteria to select the lag order.

We simulated the distribution of NCIPS setting $N = 100$, $T = 500$, and using 50,000 replications. The simulated density functions of the NCIPS and the Pesaran's CIPS Statistics are displayed in Figure 3. Both the densities show marked departures from normality. The density shows a great degree of departure from normality. The skewness and Kurtosis -3 coefficients of the NCIPS and the Pesaran's CIPS distributions are reported in Table 4. The critical values of the nonlinear CIPS test are given in Appendix 2.

3.3 The Serially Correlated Errors Case

Serial correlation can be incorporated in the model in a variety of different ways. In what follows, we use the model in Equation (4) and specify the serial correlation structure as:

$$u_{it} = \rho_i u_{i,t-1} + \eta_{it} \quad (12)$$

We first model serial correlation as above and thereafter cross section dependence as

$$\eta_{it} = \gamma_i f_t + \varepsilon_{it} \quad (13)$$

Using Equation (6) jointly with (12) above we obtain:

$$\Delta y_{it} = a_i(1 - \rho_i) + b_i(1 - \rho_i)y_{i,t-1}^3 + \rho_i \Delta y_{i,t-1} + \eta_{it} \quad (14)$$

And substituting (13) into (14)

$$\Delta y_{it} = a_i(1 - \rho_i) + b_i(1 - \rho_i)y_{i,t-1}^3 + \rho_i \Delta y_{i,t-1} + \gamma_i f_t + \varepsilon_{it} \quad (15)$$

Finally by imposing the unit root null on Equation (15):

$$\Delta y_{it} = a_i(1 - \rho_i) + \rho_i \Delta y_{i,t-1} + \gamma_i f_t + \varepsilon_{it} \quad (16)$$

Using Equation (16) and the same approach as in Appendix 1, one can obtain proxies for f_t .

We suggest in this case using the following non-linear CADF regression:

$$\Delta y_{it} = a_i + b_i y_{i,t-1}^3 + c_i y_{i,t-1}^{-3} + \sum_{j=0}^p d_{ij} \Delta y_{i,t-j} + \sum_{j=1}^p \delta_{ij} \Delta y_{i,t-j} + e_{it} \quad (17)$$

Information criteria can be used to choose the length of p .

4. Small Sample Analysis

In this section we assess the size of the nonlinear panel test defined in Equation (11) under different scenarios. Firstly, we look at power of the test in the case of weak and strong cross sectional dependence but not moving average structure for the error term. In the next section, we generalise this scenario by allowing a moving average specification for the error term and weak-strong cross sectional dependence. For comparison, in all the above experiment we also report the size of the Pesaran (2005) test when a nonlinear DGP is considered.

The data generating process (DGP) considered is the following Panel ESTAR:

$$\Delta y_{it} = \nu_i y_{i,t-1} [1 - \exp(-\theta_i y_{i,t-1}^2)] + \gamma_i f_t + \varepsilon_{it} \quad (18)$$

with $i=1, 2, \dots, N$; $t=-51, -50, \dots, 1, 2, \dots, T$; $f_t \sim i.i.d.N(0,1)$; $\varepsilon_{it} \sim i.i.d.N(0, \sigma_i^2)$; $\sigma_i^2 \sim i.i.d.U[0.5,1.5]$. We consider two scenarios for cross sectional dependence, namely low cross sectional dependence $\gamma_i \sim i.i.d.U[0,0.20]$, and high cross sectional dependence $\gamma_i \sim i.i.d.U[-1,3]$.

4.1 Size Distortion Analysis

In our size analysis below, we generate data by setting $\theta_i = 0$ for all i . Size is computed at the 5% nominal significance level. The number of replications is set to 5,000. The standard error of the computed size is 0.0031. Results for the size are reported in Table 4 below.

The test seems to have an acceptable size for large cross section dimension and somehow slightly undersized with respect to the Pesaran (2005) test.

4.2 Power Analysis

In this section we assess the power of the test defined in Equation (11) under the same DGP as above but we consider the cases of weak and strong alternatives, namely we assume for the weak alternative:

$$\theta_i = 0 \text{ for } i = 1, 2, \dots, N/2 \quad \theta_i = 0.01 \text{ for } i = N/2 + 1, \dots, N, \quad (19a)$$

while for the strong alternative:

$$\theta_i = 0 \text{ for } i = 1, 2, \dots, N/2 \quad \theta_i = 0.05 \text{ for } i = N/2 + 1, \dots, N. \quad (19b)$$

The power is computed at the 5% nominal significance level, and results are reported in Tables 5 and 6. The test we propose seems to have stronger power than the Pesaran (2005) test when the true DGP is nonlinear.

4.3 Serial Correlated Errors Case

In this section we analyze size and power of the proposed test when serial correlation is incorporated into the DGP. We consider positive serial correlation. The errors ε_{it} were generated as:

$$\varepsilon_{it} = \rho_i \varepsilon_{i,t-1} + \zeta_{it}, \quad (20a)$$

$$\zeta_{it} \sim i.i.d.N(0, \sigma_i^2), \quad (20b)$$

$$\sigma_i^2 \sim i.i.d.U[0.5; 1.5], \quad (20c)$$

$$\rho_i \sim i.i.d.U[0.2; 0.4] \text{ in the case of positive correlation,} \quad (20d)$$

$$\rho_i \sim i.i.d.U[-0.4; -0.2] \text{ in the case of negative correlation.} \quad (20e)$$

We only consider here for the power analysis the case where

$$\theta_i = 0 \text{ for } i = 1, 2, \dots, N/2, \quad \theta_i = 0.05 \text{ for } i = N/2 + 1, \dots, N, \quad (21a)$$

and high cross-sectional dependence:

$$\gamma_i \sim i.i.d.U[-1, 3]. \quad (21b)$$

The size and power are computed at 5% nominal significance level and it are based on the following non-linear CADF regression:

$$\Delta y_{it} = a_i + b_i y_{i,t-1}^3 + c_i \bar{y}_{t-1} + d_{i,0} \Delta \bar{y}_t + d_{i,1} \Delta \bar{y}_{t-1} + \delta_{i,1} \Delta y_{i,t-1} + e_{it} \quad (22)$$

$$i = 1, 2, \dots, N; t = 1, 2, \dots, T, \quad \bar{y}_t = \frac{1}{N} \sum_{i=1}^N y_{it}.$$

The test is computed as:

$$\bar{t}_{NL}(N, T) = N^{-1} \sum_{i=1}^N t_{iNL}(N, T) \quad (23)$$

where $\bar{t}_{NL}(N, T)$ is the OLS t-ratio of b_i in the above non-linear ADF regression. The number of simulation is set equal to 5,000. Table 7 below shows the results.

Both tests have a good size with the Pesaran (2005) being consistently oversized. In Table 80 we show results on the power of the test in the case when positive as well as negative serial correlation is present in the DGP. For panels of a moderate size, the gain in power from using the non-linear panel unit root test with respect to the Pesaran (2005) test is evident.

5. An Empirical Application: Real Exchange Rates

In this section we apply our test to real exchange rates against the US dollar for twenty OECD countries over the period 1973Q1-1998Q2. The data set is the same used by Murray and Papell (2002, 2004).

Since the long-run Purchasing Power Parity (PPP) relationship is one of the main components of theoretical international macroeconomic models, a large number of studies have tested this relationship by applying unit root tests to real exchange rates. Most of these studies show evidence of unit root behaviour in real exchange rates, which has become a puzzle in international finance. The growing literature on nonlinear exchange rates argues that transaction costs and frictions in financial markets may lead to nonlinear convergence in real exchange rates. Consequently, the non-mean reversion reported by linear unit root tests may be due to the fact these tests are based on a mis-specified stochastic process.

The individual statistics for our unit root test are shown in Table 9. For comparison purposes, we also report the statistics for the Pesaran (2005) test which accounts for cross section dependence but not for nonlinearity.

The Pesaran (2005) test rejects the unit root null hypothesis in only 1 out of 20 cases at all levels of significance. By contrast, the nonlinear test rejects the null in 2 cases at the 1% significance level, and in 5 cases at the 5% and 10% level. Hence our test rejects the unit root null more frequently and therefore yields stronger support for the long-run PPP.

As we argued above, univariate tests have low power and this problem is overcome by employing panel unit root tests. The results for our panel unit root test and the Pesaran panel unit root test are shown in Table 10.

The contrast between the two panel statistics is rather strong. The Pesaran (2005) test fails to reject the unit root null at all levels of significance, thus implying non-mean reversion in the whole panel of real exchange rates. On the other hand, our nonlinear panel test rejects the unit root null for the panel of real exchange rates at all levels of significance, giving support to the long-run PPP for the whole panel of OECD countries. This evidence of nonlinear mean reversion in the OECD real exchange rates may suggest that previous evidence of non-mean reversion in real exchange rates is due to using linear unit root tests.

6. Conclusion

A number of panel unit root tests allowing for cross-section dependence have been proposed in the literature. In this paper we propose a nonlinear heterogeneous panel unit root test for testing the null hypothesis of unit-root processes against the alternative that allows a proportion of units to be generated by globally stationary ESTAR processes and a remaining non-zero proportion to be generated by unit root processes. The proposed test is simple to apply and accommodates both nonlinearity and cross sectional dependence. Our test is compared to Pesaran's (2005) linear test via Monte Carlo simulation exercises, and it is found that our test holds correct size and under the hypothesis that data are generated by globally stationary ESTAR processes has a better power than the Pesaran test. We also calculate critical values for varying cross section and time dimensions which can be used in future applications of our test.

We provide an application to a panel of bilateral real exchange rate series with the US dollar from the 20 major OECD countries. In contrast to the evidence obtained by linear tests, we find evidence of nonlinear mean-reversion in the real exchange rates for the whole OECD panel that gives support to the long-run PPP hypothesis. Given the importance of the PPP in international macroeconomic models, our evidence suggests that the employment of nonlinear panel unit root tests may provide a solution to the PPP puzzle.

Given the growing literature of nonlinear models, we believe that the development of panel nonlinear unit root tests has large potential in macroeconomic and financial applications. Evidence indicates that different time series may follow different nonlinear specifications. Consequently, one could consider unit root tests with different types of transition functions that allow for asymmetric dynamic adjustment. Another extension would be to allow for different transition variables. Further applications of our tests and theoretical extensions are left for future work.

Appendix 1

Proof of Lemma 1

We assume that the error term u_{it} in (8) follows a stationary process, for all i , with summable

auto-covariance given by $u_{it} = \sum_{l=0}^{\infty} a_{il} \zeta_{i,t-l}$, with $\zeta_{i,t}$ being a zero mean random variable

with variance matrix defined by I_{l+1} and finite fourth order moment.

The variance of u_{it} is finite and given by:

$$\text{Var}(u_{it}) = \sum_{l=0}^{\infty} a_{il}^2 = \sigma_i^2 \leq \sigma^2 < \infty. \quad (24)$$

First note that, after using cross sectional averages, Equation (8) can be written as:

$$\Delta y_{\varphi t} = \omega_{\varphi} y_{\varphi t-1} + \gamma_{\varphi} f_t + u_{\varphi t} \quad (25)$$

With $\Delta y_{\varphi t} = \sum_{i=1}^N \varphi_i \Delta y_{it}$; $y_{\varphi t-1} = \sum_{i=1}^N \varphi_i y_{i,t-1}$; $\omega_{\varphi} = \sum_{i=1}^N \varphi_i \omega_i$; $\gamma_{\varphi} = \sum_{i=1}^N \varphi_i \gamma_i$ and

$$u_{\varphi t} = \sum_{i=1}^N \varphi_i a_{it}.$$

Assuming that $\gamma > 0$, then f_t can be approximated as follows:

$$f_t \approx \frac{1}{\gamma_{\varphi}} \Delta y_{\varphi t} - \frac{1}{\gamma_{\varphi}} \omega_{\varphi} y_{\varphi t-1} - \frac{1}{\gamma_{\varphi}} u_{\varphi t} \quad (26)$$

And since $Var(\bar{u}_{\phi t}) = \sum_{i=1}^N \bar{\phi}_i^2 (\sum_{i=0}^{\infty} \bar{a}_i^2)$ and $Var(\bar{u}_{\phi t}) \leq \bar{\sigma}^{-2} (\sum_{i=1}^N \bar{\phi}_i^2) = O(\frac{1}{N})$, It follows that

as $N \rightarrow \infty$, $E(\bar{u}_t) = 0$. consequently the factor \bar{f}_t can now be approximated by:

$$\bar{f}_t \approx \frac{1}{\bar{\gamma}_\phi} \Delta \bar{y}_{\phi t} - \frac{\bar{\omega}_\phi}{\bar{\gamma}_\phi} \bar{y}_{i,t-1}^3 \quad (27)$$
